

Finally,  
empirical  
results!

**A rare allele spends more time as a heterozygote than a homozygote**

A heterozygote disadvantage corresponds to a rare allele disadvantage

With underdominance, if starting at a high enough frequency, an allele less fit than wildtype can stably fix in a population.

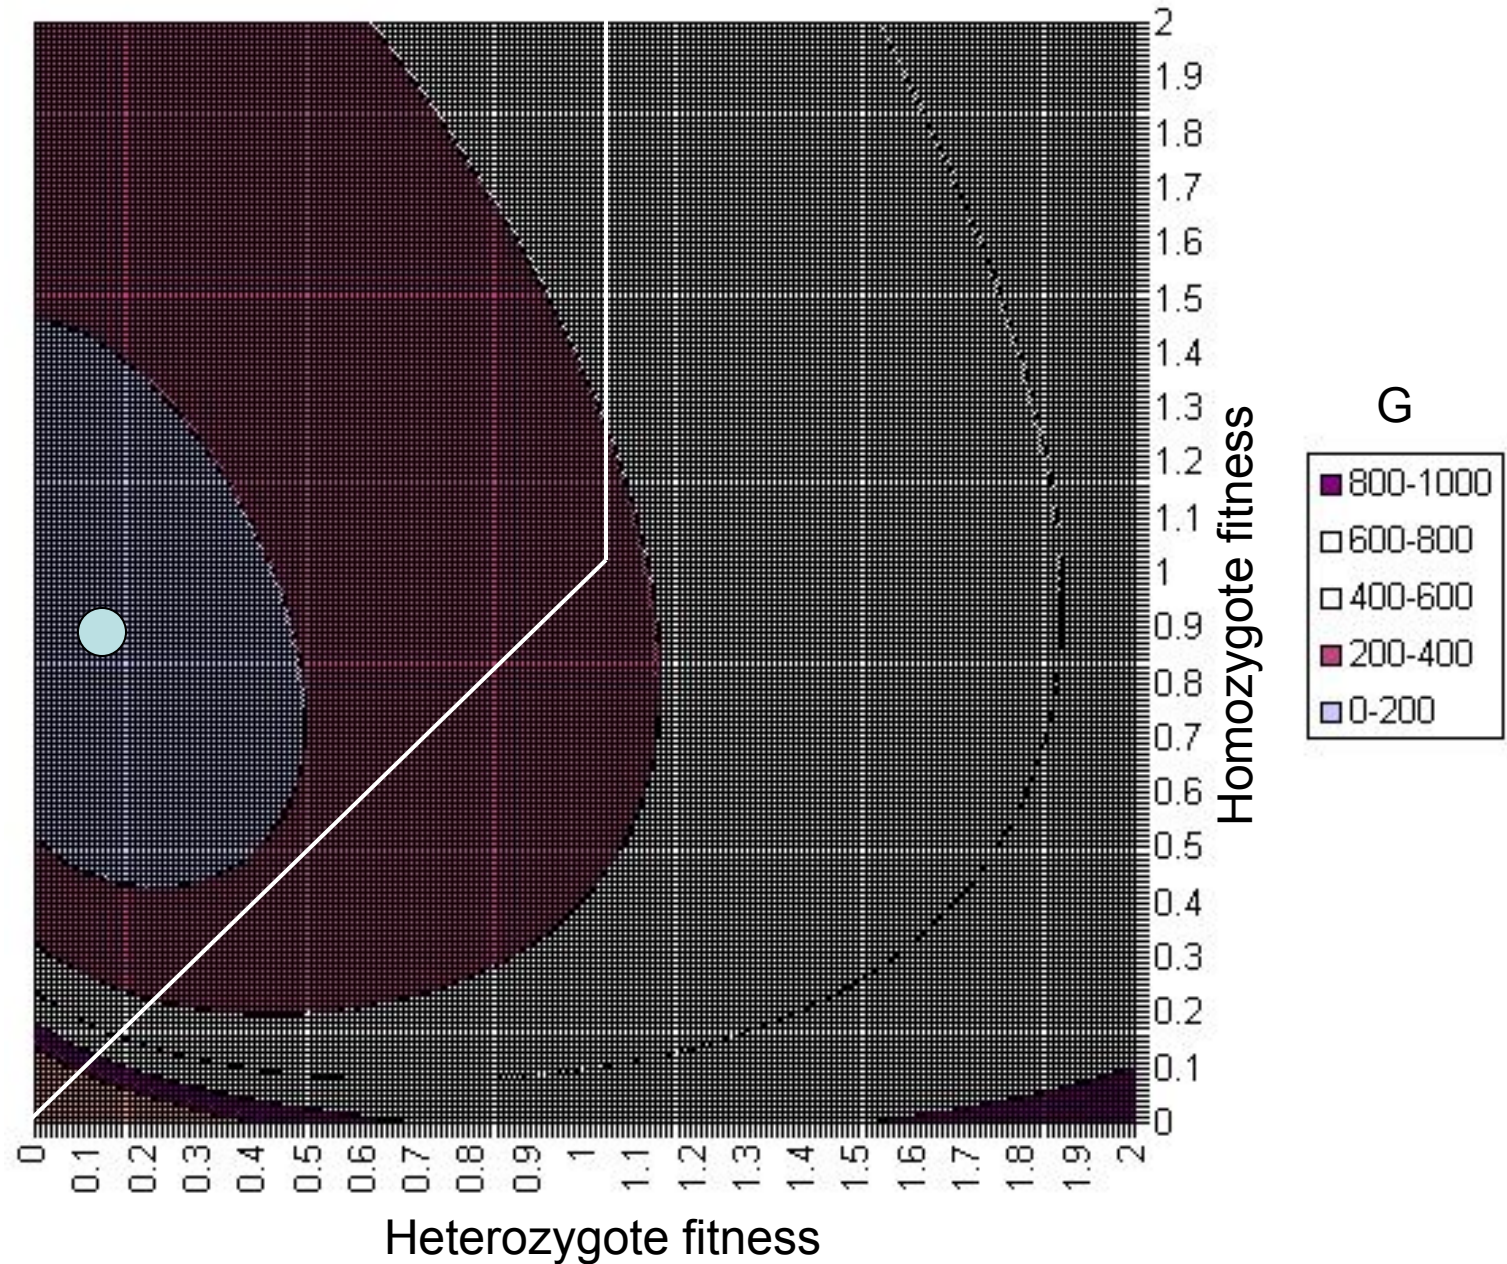

# Allele frequency changes over replicated populations

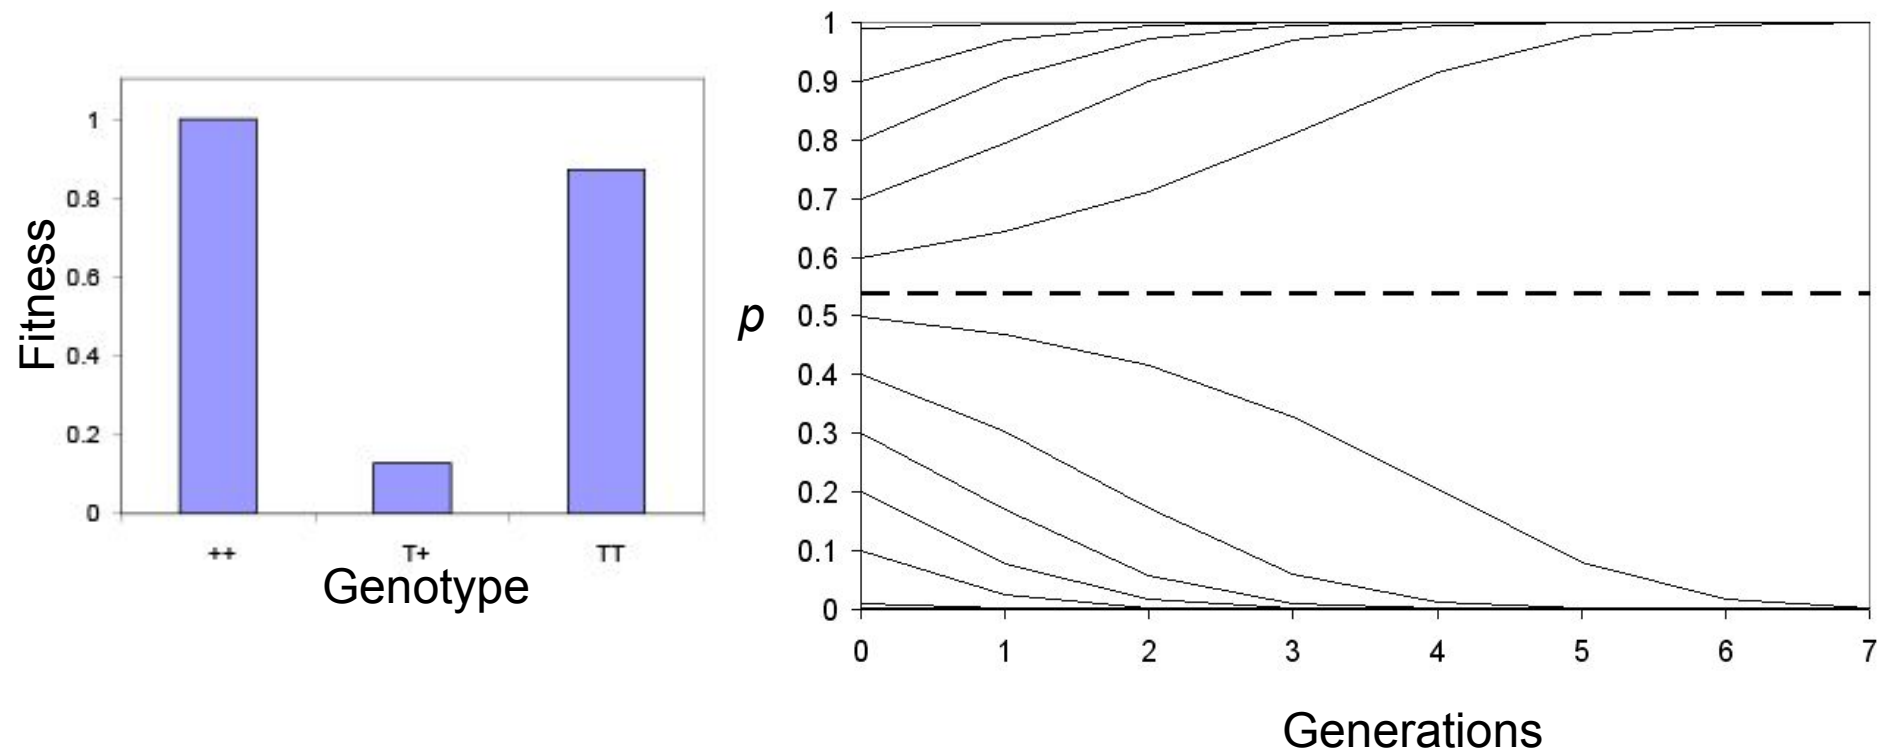

The model is fit to the data to estimate relative genotype fitnesses

The maximum-likelihood estimate predicts the following fitness configuration and changes in allele frequency.

# Theory and Data

# Stability of an underdominant polymorphism in the presence of migration

Philipp M. Altrock<sup>a\*</sup>, Arne Traulsen<sup>a†</sup>, R. Guy Reeves<sup>b‡</sup>, and Floyd A. Reed<sup>b\*</sup>

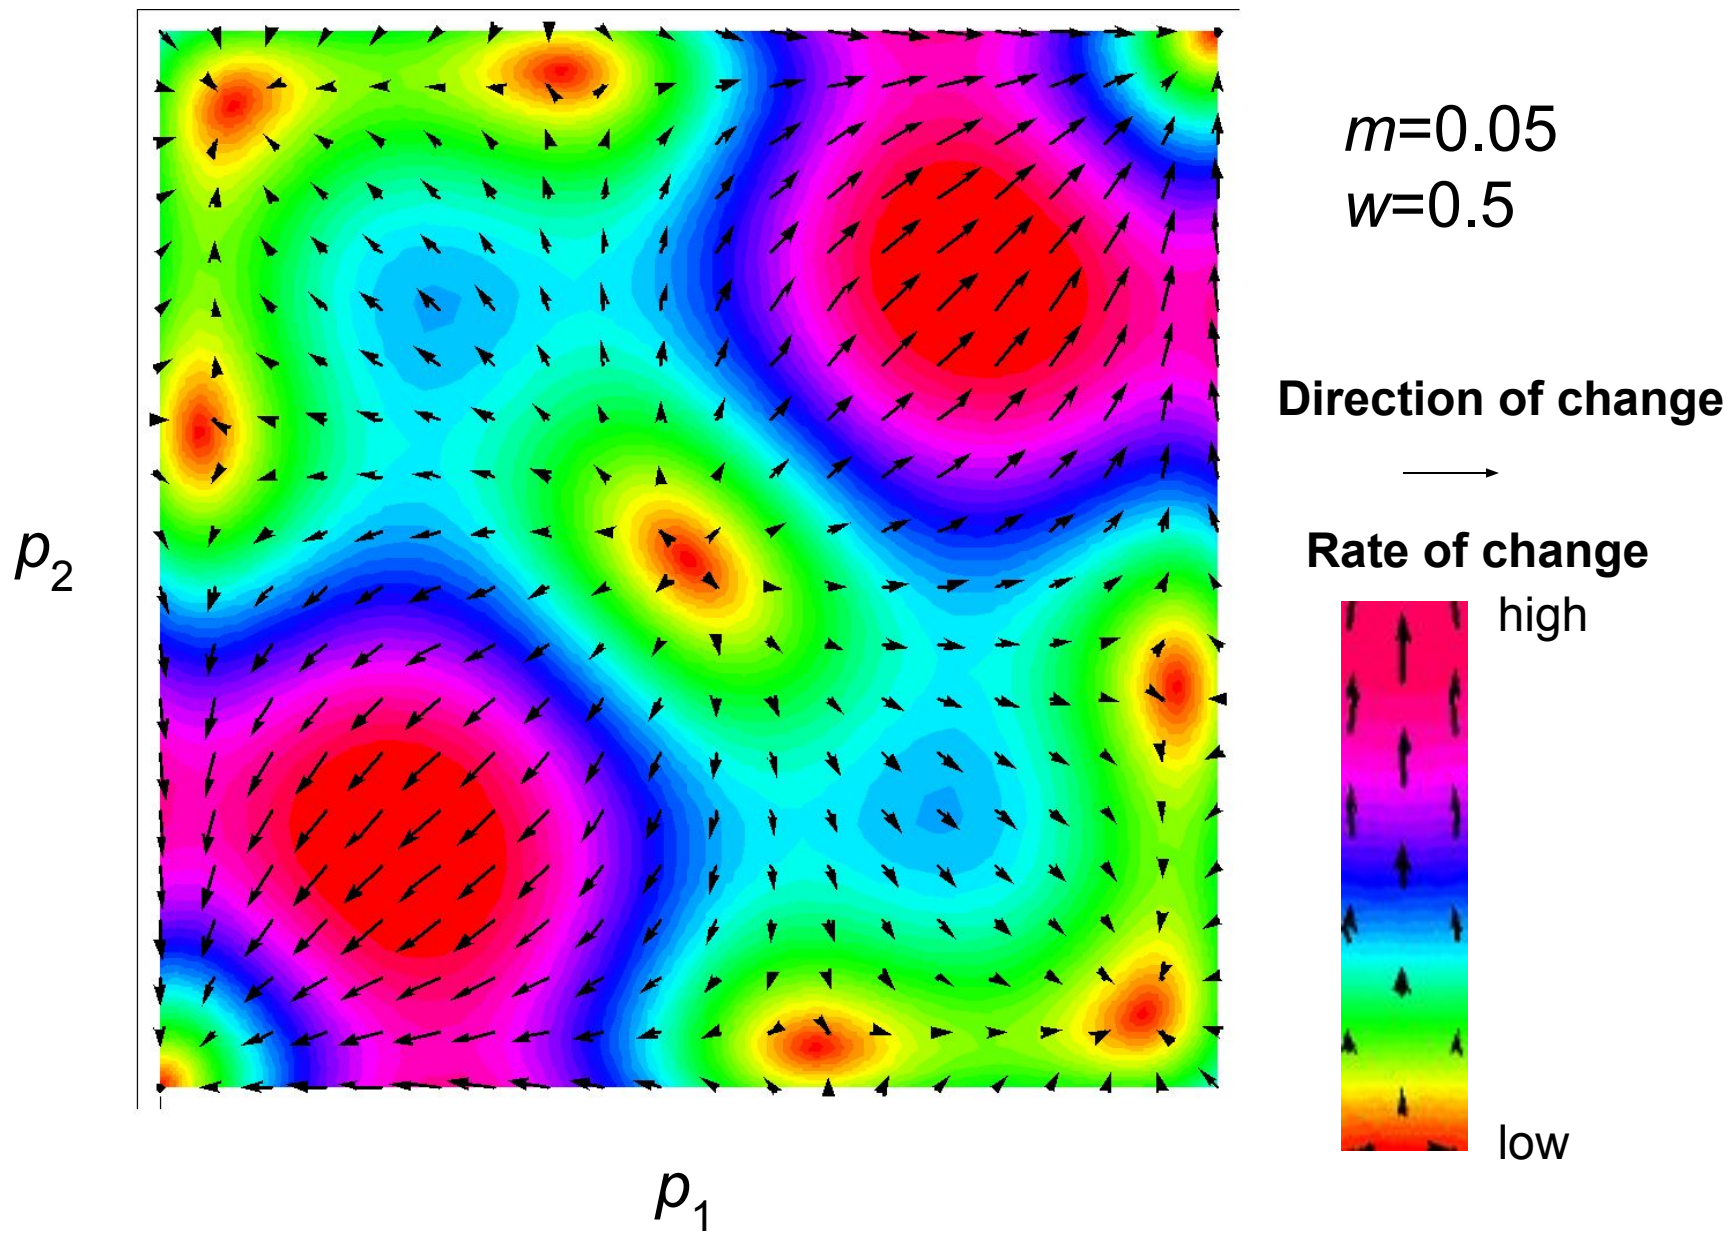

In revision at JTB

G. Pryor 2003

The simplest model to investigate the spatial properties of underdominance is one of a single locus in two populations exchanging migrants each generation.

$$m=0.1$$
$$w=0.5$$

Direction of change

Rate of change

high

low

The maximum migration rate that allows local underdominant stability.

## Prediction of maximum migration rate with asymmetric fitness.

$$\mu_2(\omega) = \frac{1}{4} \left( 3 - \sqrt{5 + 4\omega} \right)$$

$$\mu_w(\omega, \nu) = \mu_3(\omega, \nu)(1 - \nu) + \frac{\mu_2(\omega)(\nu - \omega)^2}{(1 - \omega)^2}.$$

$$\mu_3(\omega, \nu) = \frac{\nu(2 - 2\omega + \nu) - \omega^2 - 2\sqrt{\nu(1 + \nu - 2\omega)(\nu - \omega^2)}}{(\nu - \omega)^2}.$$

**or about 14% migration**

## First generation, 2-population results!

So far, first generation, only homozygotes have been present.  
This is directional selection with no spatial stability.

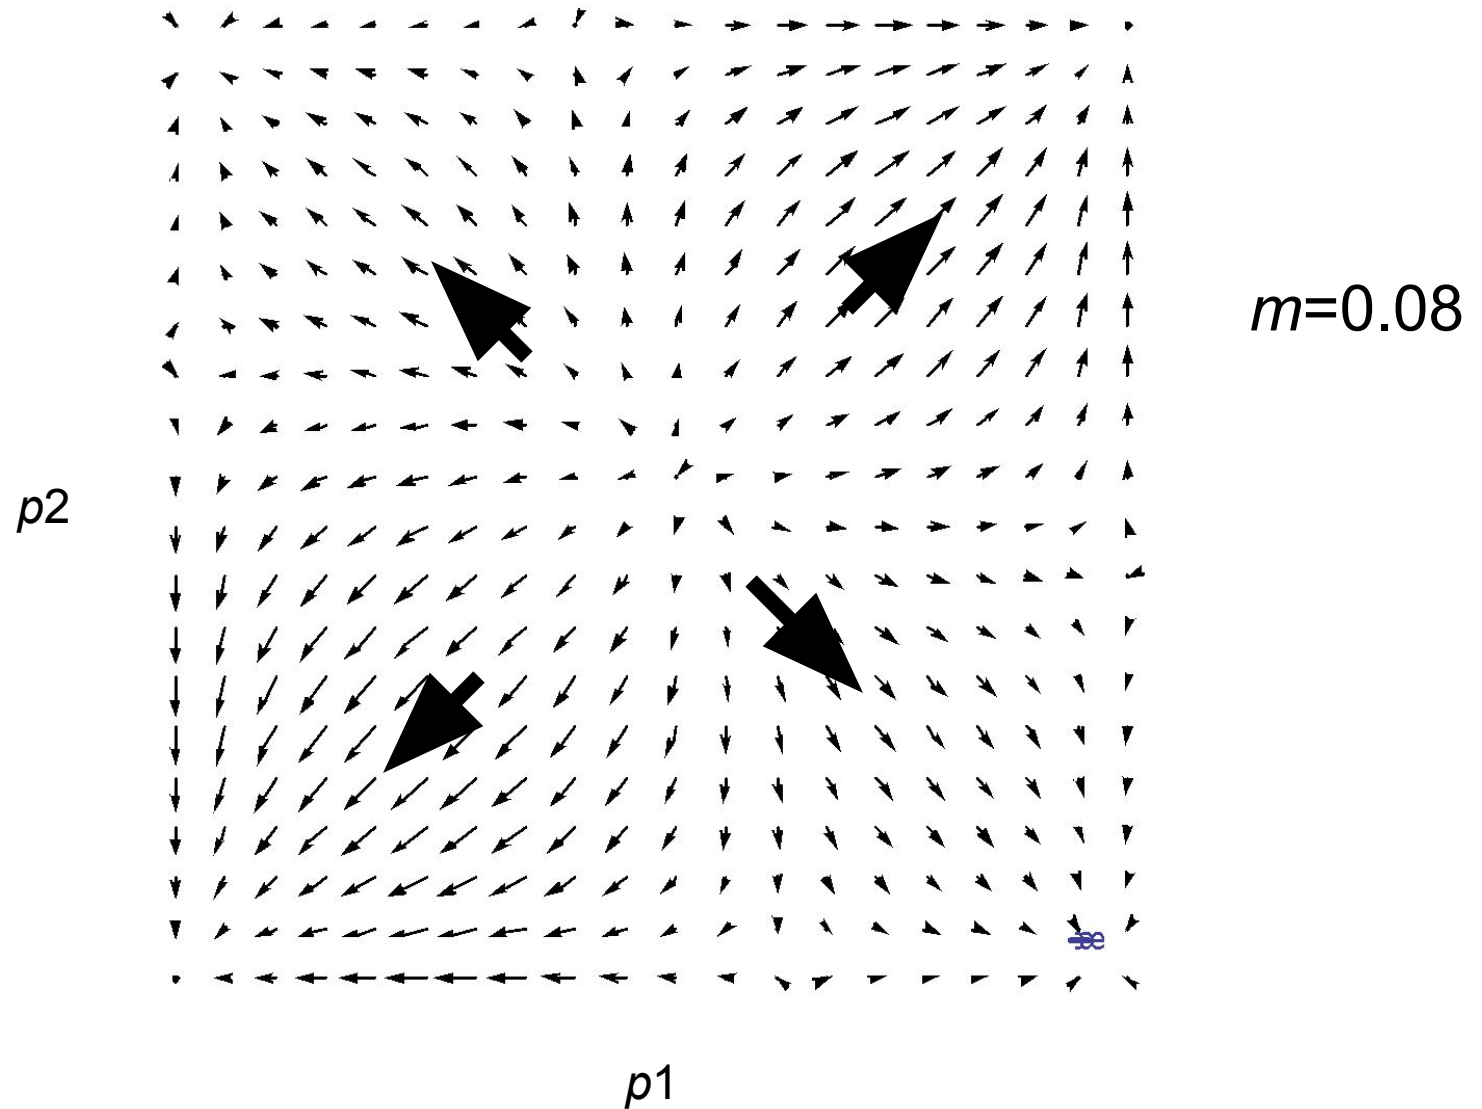

# Directional Selection

In the next generation (next week!) heterozygotes should appear and give a stabilizing effect.

# Underdominance, pushing toward the corners

# Potential period of stability

No stability

$m=0.16$

## **Conclusion**

**We have created an underdominant system!**

**In a large population, it (should) allow local stable transformations with migrations rates as high as 14%!**

**Next:**

**Follow more generations**

**Estimate effective population size in our experiments**

**Simulate the effects of genetic drift on stability.**

**Develop a more complete model of the effects of  
mating prior to migration (and mating  
discrimination)**

Extra slides for questions

In contrast to the single-population prediction, underdominance can maintain a stable polymorphism among multiple populations connected by migration.

In contrast to the single-population prediction, underdominance can maintain a stable polymorphism among multiple populations connected by migration.

In contrast to the single-population prediction, underdominance can maintain a stable polymorphism among multiple populations connected by migration.

However, if the migration rate is too high, the system behaves like a single population and polymorphism is lost.

# Potential period of stability

$$m=0.04$$

# Potential period of stability

No stability

$m=0.16$

No stability

$m=0.2$

Mating prior to migration has a destabilizing effect.

The G-test (or likelihood ratio or maximum likelihood test) is similar to the chi-square test.

$$\chi^2 = \sum_{ij} \frac{(O_{ij} - E_{ij})^2}{E_{ij}}$$

$$G = 2 \sum_{ij} O_{ij} \ln \left( \frac{O_{ij}}{E_{ij}} \right)$$

Expected values can be generated according to the Wright-Fisher model. Stochastic drift is not included in the model but is not expected to bias results (however the more data the better to average this out). G is expected to the Chi-square distributed.

Suggested/used for population bottle data by Clark *et al.* 1989

Weighted by number of alleles in each genotype

Early work failed to achieve underdominance with wildtype heterozygotes.

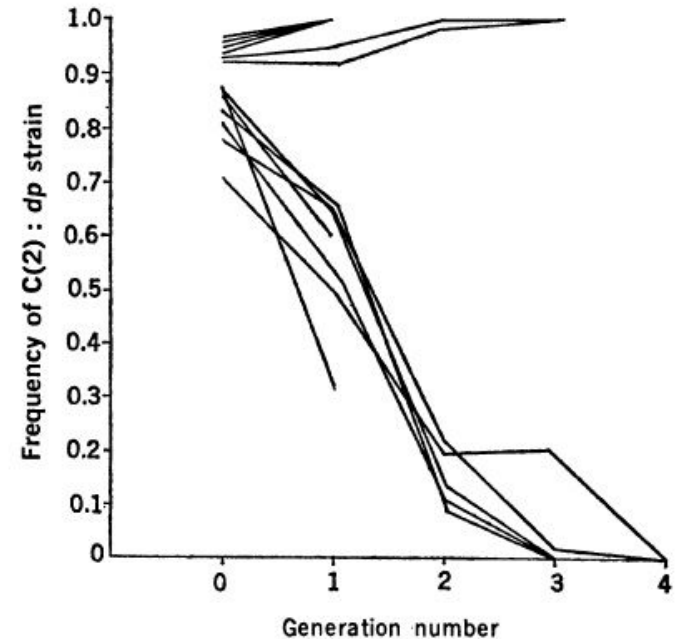

Fig. 6 (left). Change in frequency of C(2) : dp strain in competition with C(3) : ri strain. The unstable point is about 0.5. Fig. 7 (right). Change in frequency of C(2) : dp strain in competition with structurally wild-type strain. The unstable point is about 0.9.
